Photocatalysis by Calcium Hydroxyapatite Modified with Ti (IV)

Masato Wakamura

(Manuscript received February 3, 2005)

Colloidal Ca\textsubscript{10}(PO\textsubscript{4})\textsubscript{6}(OH)\textsubscript{2} hydroxyapatite (HAP) particles doped with Ti(IV) ions in different atomic ratios, Ti / (Ca + Ti) = X\textsubscript{Ti}, by a coprecipitation method were characterized by JEOL transmission electron microscope (TEM), UV, Elmer Fourier transform infrared (FTIR) spectrophotometer, X-ray photoelectron spectroscopy (XPS), and Perkin-Elmer-induced coupled plasma spectrometer (ICP-AES). The photocatalytic activity of the modified HAP particles was examined by decomposition of acetaldehyde and albumin and bactericidal test by colon bacilli. The deodorization ability was measured using a six-stage sensory method. Ca(II) of HAP was substituted by Ti(IV) in a one-to-one ratio at X\textsubscript{Ti} \leq 0.1. When doped at X\textsubscript{Ti} > 0.1, irregular particles of amorphous titanium phosphate were formed besides long, rectangular particles of HAP. X\textsubscript{Ti} of the surface phase of the particles was much less than that of the whole particles; Ti(IV) is less contained in the surface phase than the bulk one. A UV beam was absorbed by Ti(IV)-modified HAP particles but not by the unmodified particles. The decomposition of acetaldehyde and albumin by Ti(IV)-doped particles was found under UV irradiation, while the unmodified HAP particles were inactive for the decomposition of both materials. Further, unlike TiO\textsubscript{2}, Ti(IV)-doped HAP showed a bactericidal function in the dark. A Ti(IV)-doped HAP adhesion filter demonstrates a high deodorization performance.

1. Introduction

Recently, titanium dioxide, TiO\textsubscript{2}, has been receiving much attention as a photocatalyst that photo-oxidizes organic substances in both water and air.\textsuperscript{1,2} Synthetic calcium hydroxyapatite Ca\textsubscript{10}(PO\textsubscript{4})\textsubscript{6}(OH)\textsubscript{2}, referred to as hydroxyapatite (HAP), is biologically important and is used as a bioceramic and adsorbent for biomaterials because it shows an excellent affinity for organic compounds such as proteins. Hence, it is of interest for preparing composite materials of TiO\textsubscript{2} and HAP for photocatalytic decomposition of biomaterials such as proteins and lipids. Nonami et al. proposed a new structure for TiO\textsubscript{2}-HAP composite films in which a porous HAP layer forms on a TiO\textsubscript{2} layer on a substrate in a pseudo body solution.\textsuperscript{3} However, this composite structure is inefficient for photocatalysis, which requires UV irradiation of the TiO\textsubscript{2} layer. We attempted to develop a novel photocatalyst with a high affinity for biomaterials by atomic-level composition of a photocatalytic material and HAP, which was realized by modifying HAP particles with Ti(IV). The modification of HAP particles was performed by coprecipitation and ion exchange methods. Suzuki et al. have found that Ca(II) of HAP can be exchanged with various metal ions in aqueous media.\textsuperscript{4-12} However, the surface structure and properties of the metal-substituted HAP have not been clarified. Ribeiro et al. have studied the surface of HAP modified with Ti(IV) ions by immersion methods\textsuperscript{13} and indicated the formation of a titanium phosphate, Ti(HPO\textsubscript{4})\textsubscript{2}\textsubscript{n}H\textsubscript{2}O (n = 1-3), which probably has a double-layered
structure.\textsuperscript{14} Weiser et al. have coated metal Ti with HAP by doping and diffusing Ca and P elements into the metal before the coating to obtain a high-quality HAP film on the metal Ti surface.\textsuperscript{15} On the other hand, Zeng et al. have studied the adsorption of albumin on calcium phosphate (CaP) and Ti films deposited on a germanium ATR crystal by ion beam sputter deposition from HAP and metal Ti targets and found that the CaP film adsorbs greater amounts of albumin than the surface of metal Ti; CaP shows a higher affinity for protein than metal Ti.\textsuperscript{16} Since the HAP surface is known to show a high affinity for albumin,\textsuperscript{17,18} HAP is used as an adsorbent in column chromatography for separating proteins. The bactericidal effects of Ag-HAP thin films on alumina have been reported by Feng et al.\textsuperscript{19} Although Ti(IV)-modified HAP is anticipated to show a bactericidal effect, there has been no study on the bactericidal characteristics of this material.

Wakamura et al. previously investigated the surface structure and composition of HAP particles modified with various metal ions by coprecipitation and ion-exchange methods.\textsuperscript{20-22} In the present study, HAP particles modified with Ti(IV) by a coprecipitation method were characterized by various techniques. The photocatalytic activities of the well-characterized modified HAP particles were examined by decomposition reactions of acetaldehyde and albumin.

The deodorization ability of an adhesion filter incorporating the modified HAP particles was evaluated using a sensory six-stage odor-strength method.

Based on the obtained results, we examined the surface structure and photocatalysis of the modified HAP particles. Further, the bactericidal function of the materials was examined using a colon bacillus and a noble photocatalyst was developed.

\section{Experiments}
\subsection{Materials}
Colloidal HAP particles doped with Ti(IV) were prepared by coprecipitation; Ca(NO\textsubscript{3})\textsubscript{2} and Ti(SO\textsubscript{4})\textsubscript{2} were dissolved in 1 dm\textsuperscript{3} deionized-distilled water free from CO\textsubscript{2} at different atomic ratios: Ti/(Ca + Ti) = X\textsubscript{T} from 0 to 0.8. The total amount of Ca and Ti in the solutions was held at 0.1 mol; 0.060 mol H\textsubscript{3}PO\textsubscript{4} was added to the solutions, and the solution pH was adjusted to 9 by adding a 15 mol dm\textsuperscript{-3} NH\textsubscript{4}OH solution. The resulting suspension was aged in a capped Teflon vessel at 100°C for 6 h. The resulting precipitates were filtered off, washed with 5 dm\textsuperscript{3} deionized and distilled water, and finally dried in an air oven at 70°C. Ninhydrin and albumin supplied by Wako Pure Chemicals were used as received.

\subsection{Characterization}
The HAP particles thus modified with Ti(IV) were examined by various conventional methods as follows. The morphology of the particles was observed using a JEOL transmission electron microscope (TEM) at an accelerating voltage of 200 kV. The samples for TEM were prepared by a dispersing method. X-ray diffraction (XRD) patterns were taken by a powder method using a Shimadzu high-intensity diffractometer with a rotating cathode using CuK\textsubscript{α} radiation (50 kV and 200 mA). Transmission IR spectra were recorded in vacuo using a Perkin-Elmer Fourier transform infrared (FTIR) spectrophotometer using a self-supporting disk method in a vacuum cell. The sample powders (30 mg) were pressed into disks of 1 cm diameter under 572 kg cm\textsuperscript{-2}. Before taking the spectra, the sample disks were outgassed at 300°C for 2 h. Reflection UV-VIS spectra were taken using a UV spectrometer (JASCO V-560) at 200 to 400 nm. The specific surface area was calculated by applying the BET equation to the N\textsubscript{2} adsorption isotherm measured at −196°C using an automatic volumetric apparatus.

\subsection{Chemical analysis}
The Ti and P contents were determined by a Perkin-Elmer-induced coupled plasma spectrometer (ICP-AES) employing wavelengths of 317.933
M. Wakamura: Photocatalysis by Calcium Hydroxyapatite Modified with Ti (IV)

(Ca), 334.941 (Ti), and 213.618 nm (P). The samples for ICP-AES were dissolved in a dilute HNO₃ solution. X-ray photoelectron spectroscopy (XPS) was done using a Perkin-Elmer spectrophotometer with MgKα radiation (20 kV and 30 mA), with the samples mounted on the sample holder by carbon tape.

2.4 Acetaldehyde decomposition test

The photocatalytic activities were estimated from decomposition of acetaldehyde vapor under 1 mW cm⁻² UV irradiation. The samples used for photocatalysis were HAP modified at Xₜᵢ = 0 and 0.1. The sample weight was decided by adjusting the surface area of the samples to a constant value of 85 m² using the BET-calculated surface area. The samples were settled in the bottom of a 500 cm³ cylindrical glass vessel sealed using a 5 mm-thick quartz plate with an O-ring. The air was replaced by a mixed gas (N₂: 80%, O₂: 20%) introduced into the vessel through the gas inlet, and then acetaldehyde vapor was injected into the vessel and the vessel was stored in darkness to achieve equilibrium. Then, irradiation by ultraviolet light at 1 mW cm⁻² followed by further storage in darkness were repeated at 24 h intervals. After the reaction, the concentrations of acetaldehyde and CO₂ in the reaction vessel were determined using a gas chromatograph (FID).

2.5 Ninhydrin test of albumin decomposition.

The affinity for biomaterials and photocatalytic activities were estimated from adsorption and decomposition of albumin. The ninhydrin test was employed to identify albumin before and after the decomposition reaction. Samples of 1 g HAP modified at Xₜᵢ = 0 and 0.1 and 1 g TiO₂ were immersed in 1 g dm⁻³ albumin solutions at 30°C for 12 h. The particles were filtered, washed with 10 dm³ deionized distilled water, and dried in an air oven at 50°C. Each sample was divided into two 0.5 g parts; one was kept in a lightproof box and another was irradiated by 1 mW cm⁻² UV light for 24 h at room temperature. Finally, the samples were sprayed with a ninhydrin indicator and dried in an air oven at 150°C.

2.6 Bactericidal test by *Escherichia coli* (E. coli)

The suspensions of HAP modified at Xₜᵢ = 0 and 0.1 and TiO₂ homogeneously dispersed in silica sols were deposited on glass plates (5 × 5 cm) by a spin-coating method. The films on glass were sterilized by drying at 180°C for 30 min. E. coli cells (IFO 3310 strain) were grown aerobically in 2.5 cm³ of nutrient broth (Daigo: Nippon Seiyaku) at 30°C for 16 to 18 h. The cells were centrifuged at 4000 rev min⁻¹ and suspended in sterilized water with appropriate dilution. E. coli cell suspensions (150 × 10⁶ dm⁻³, 2 × 10⁵ cells cm⁻³, total 3 × 10⁴ cells) were pipetted onto glass plates coated with HAPs (modified at Xₜᵢ = 0 and 0.1) and TiO₂, spread out to form a liquid film of approximately 1 cm in diameter, and placed in an airtight illumination chamber to prevent drying. The chamber was illuminated with a 15 W black light, and the light intensity as measured using a UV radiometer (UVR-36, Tepcon) at the sample position was 1.0 mW cm⁻² with peaks at around 360 nm. After the illumination, the cells were removed using a gauze patch and collected in a 0.15 mol dm⁻³ NaCl solution. This solution was spread onto nutrient agar medium (Nissui: Standard Method Agar, Nissui Seiyaku) and incubated for 24 h to determine the number of viable cells in terms of colony-forming units.

2.7 Deodorization ability test

We made an air cleaner that uses an adsorption filter incorporating HAP modified at Xₜᵢ = 0.1.

The air cleaner was placed in a 1 m³ box filled with the odors of cigarettes and rotten fish, and the strength change in these odors was assessed using a six-stage sensory method.
3. Results and discussion

Figure 1 shows TEM micrographs of Ti(IV)-doped HAP particles. The HAP particles formed at $X_{Ti} \leq 0.1$ are short rods. The particles formed at $X_{Ti} \geq 0.5$ are a mixture of long rectangular and irregular particles, although Figures 1 (d) and (e) show only long rectangular and irregular particles, respectively. The irregular particles increased with an increase of $X_{Ti}$. Although the detailed reason for the formation of the long particles remains unclear, the charge difference between Ca(II) and Ti(IV) seems to influence the particle formation of HAP, as was found in a previous study on modification with Cr(III).\(^{19}\)

Figure 2 shows XRD patterns of the products at different $X_{Ti}$. Their peak intensity was lowered by increasing $X_{Ti}$ at $X_{Ti} \leq 0.5$, and the products at $X_{Ti} = 0.8$ were poorly crystallized. Except for the product at $X_{Ti} = 0.8$, the patterns are characteristic of HAP (JPCDS 9-432), verifying that the long rectangular particles formed at $X_{Ti} \geq 0.5$ are well-crystallized HAP. This finding suggests that HAP crystals can be doped with Ti(IV) up to $X_{Ti} = 0.1$.

To determine the composition of the products, Ca, Ti, and P in the formed particles were assayed by ICP-AES. Figure 3 plots the Ca(II) and Ti(IV) ion contents against $X_{Ti}$ with triangles and circles, respectively. The increase of Ti(IV) in the formed particles accompanies an equivalent decrease of Ca(II), which means that Ti(IV) in the crystal of HAP is present as a divalent ion such as $[\text{Ti(OH)}_2]^2+$ or $[\text{Ti(HPO}_4)_2]^2+$. Figure 4 plots $X_{Ti}$ of whole particles and the surface phase of particles as determined by ICP-AES and XPS, respectively. For all the materials, $X_{Ti}$ of the surface phase $(X_s)$ was less than that of whole particles $(X_w)$, which can be interpreted by considering that

Figure 4
Atomic ratios $X_{Ti}$ of Ti(IV)-modified HAP particles.

$X_{W}$: ratio in whole particles, $X_{S}$: ratio in surface phase.
Ti(IV) is precipitated more easily than Ca(II) and therefore $X_{Ti}$ will be higher in the inner part of particles. $X_{W}$ is larger than $X_{Ti}$ in the starting solutions, implying that Ti(IV) is incorporated into the particles more than Ca(II). These results are ascribed to the fact that Ti(IV) has a higher hydrolysis constant than Ca(II).

Figure 5 shows FTIR spectra of the HAP particles modified with Ti(IV) by coprecipitation at various $X_{Ti}$.

Figure 6 shows the reflection UV-VIS spectra of the products at varied $X_{Ti}$ along with the spectrum of TiO$_2$ [(d)]. The UV absorption
above ca. 370 nm is observed in the samples modified at X_{Ti} = 0.01 and 0.1 [(b) and (c)], but not in the unmodified HAP [(a)]. As X_{Ti} increases, the absorbance rises to that of TiO_2. These results clearly imply that the surface of HAP particles is modified by substitution with Ti(IV).

Figure 7 plots the concentrations of acetaldehyde and CO_2 against the UV irradiation time. It is clearly seen in Figure 7 (b) that 1) CO_2 is increased (open circles) and acetaldehyde is decreased (closed circles) by irradiating the material modified at X_{Ti} = 0.1 and 2) on stopping the irradiation, the concentrations of acetaldehyde and CO_2 are essentially unchanged. Whereas, as shown in Figure 7 (a), the unmodified sample shows a smaller concentration change of CO_2 and acetaldehyde than the modified sample. Therefore, it can be confirmed that Ti(IV)-modified HAP exhibits a higher photocatalytic activity than the unmodified HAP.

Figure 8 shows the results of the ninhydrin color test: the photographs of TiO_2 [(a)], unmodified HAP [(b)], and Ti(IV)-modified HAP [(c)] irradiated and non-irradiated by UV after albumin adsorption. TiO_2 shows no ninhydrin color under UV irradiation and non-irradiation, although a slight blue color is detected due to strongly adsorbed albumin. The unmodified HAP is colored by ninhydrin under UV irradiation and non-irradiation. The Ti(IV)-modified HAP is colored only under UV non-irradiation. These results indicate that TiO_2 does not strongly adsorb albumin, whereas the unmodified HAP adsors albumin but shows no photocatalytic decomposition activity and Ti(IV)-modified HAP adsors albumin and decomposes it by photocatalysis.

Figure 9 compares the results of the bactericidal test for the colon bacilli. TiO_2 gives rise to essentially no photocatalysis in the dark and kills only less than 10% of the bacilli, while TiO_2 kills 80% of the bacilli under UV irradiation. On the other hand, Ti(IV)-modified and unmodified HAPs show bactericidal effects even in the dark, killing ca. 50% of the bacilli. It should be noted that the bactericidal effect of Ti(IV)-modified HAP was enhanced by UV irradiation and only ca. 30% of the bacilli survived after UV irradiation. These findings indicate that Ti(IV)-modified HAP exhibits a higher bactericidal effect than TiO_2, both in the dark and under UV irradiation.

Figure 10 shows the results of the sensory

six-stage odor-strength test. As can be seen, there is a high deodorization of cigarette and rotten fish odors.

The Ti(IV)-modified HAP generates positive holes (h⁺) as well as TiO₂ catalysts. These positive holes interact with adsorbed H₂O to yield hydroxyl radicals (OH⁺), which have a strong oxidation ability that decomposes various organic compounds and have a bactericidal effect. To verify the details of this mechanism, further analysis of the band structure of Ti(IV)-modified HAP is required.

4. Conclusion

We can draw the following conclusions from the results obtained from this study. Ca(II) ions in HAP crystals are exchanged with Ti(IV) up to atomic ratios of X₁, =0.1. The added Ti(IV) exists in HAP crystals as divalent cations such as [Ti(OH)₂]²⁺ and [TiHPO₄]²⁻. Ti(IV)-substituted HAP has surface OH groups originating from HPO₄²⁻ and OH⁻ coordinating to Ti(IV). HAP particles penetrated by Ti(IV) absorb UV light at wavelengths less than 380 nm, so they exhibit photocatalytic activity in the oxidation and decomposition of acetaldehyde. This characteristic of Ti(IV)-modified HAP resembles the case of oxidative decomposition of organisms by TiO₂. However, HAP has a high affinity for organic compounds such as proteins, although TiO₂ shows no such affinity. Therefore, distinct from TiO₂ photocatalysts, Ti(IV)-modified HAP has both an adsorption affinity and photocatalytic activity for organic compounds. To make matters better, Ti(IV)-modified HAP shows a bactericidal effect even in the dark, whereas TiO₂ shows it only under UV irradiation.
